With the rapid development of information and communication technology, we can access a wide range of network data. These data sets offer us the opportunity to analyze and predict network revolution. In this paper, we have proposed a way which combines link prediction methods to solve the traffic congestion problem. Based on the congested traffic line, we will predict the likelihood of new routes. One different from the link prediction problem is that in the traditional link prediction our goal was to find the edges to be created in the future, while in our traffic problem we have already known the edges to be predicted, our goal was to predict the sequence of these edges. Besides the algorithms we have proposed, we have conducted various experiments to prove our methods to be effective to reduce the congestion index of the traffic. This work is an exploration of using link prediction method in the traffic problem, it provides a new view in the traffic control problem and may further affect the link prediction usage in the traffic field.

## INTRODUCTION

Since 1736 Euler defined and solved the Seven Bridges problem of Knigsberg, there was not much ground breaking development in the complex network research area until 1960s, when the Erdos-Renyi random graph model (ERmodel) was introduced. A new wave of research was set off by Watts and Strogatz who published a paper about the small world effect in 1998 and introduction of the scalefree network model by Barabasi and Albert one year later. The number of publications in the last 17 years in complex networks is more than the total appearance before 1999. In our living world, many systems can be modeled as complex networks where nodes represent the basic units of a system and links stands for the interactions between the nodes[1]. Complex networks has been a research field focus on not only science but also engineering for the last few decades[2–11].

Modern world depends greatly on the efficient operation of many critical infrastructures such as Internet, airlines, power grid, highway networks and so on[12]. \*\*\*\*\* 230 Recently, most attentions has been given to the traffic congestion problem in transportation networks Knowledge on traffic congestion is relevant to the design and control of real traffic systems network design concerns how to deploy network resources In this paper, np 1.midicaterecover 2. 3.

Researches on such fields realize that such systems can be modeled within the framework of complex networks. Traffic on such networks is a vital problem. Recently, more attentions has been given to the traffic congestion problem in transportation networks, understanding network congestion has become a subject of intense research in this field. Knowledge on traffic transportation is relevant to the design and engineering of real systems , for example how to deploy network resources, how to route traffic efficiently and how to mitigate congestion. A networks transmission capacity is the maximal amount of traffic flow that the network can handle without causing congestion[55]. Increasing network transmission capacity is one of the major goals for network design and engineering.

**As the best as we know, there are three aspects efforts in enhancing the transmission capacity.**

The first aspect lies in the discussion of topology. Zhao et al. proposed two models to address the problem: (1) The capacity of delivery of each node is proportional to its degree; (2) The delivery capacity of each node is proportional to its betweenness. They have found that in the first model, random networks and scale-free networks are more tolerant to congestion than regular networks and Cayley trees. For the second model, the crowded degree is independent of the network topology and size, so this model may be useful for communication protocols[39]. In their work, Boccaketti et al. thought that in transportation networks, the factors that affect the global performance are the traffic load of a road, that is to say the number of the passengers in the airports or the passengers in the subways. They also doing

experiments to remove a small fraction of nodes simulating the breakdown of an Internet router or transportation system, such removals will change the shortest paths between nodes and the distribution of the loads and creating overloads on some nodes. After the experiment, they found that homogeneous network does not experience cascading failures due either to random breakdown or to intentional attacks. While for the heterogeneous network, cascades triggered by the attack on a key node can cause serious congestion problem, homogeneous networks appear to be more resistant to cascading failures than the heterogeneous ones[43]. Toroczkai et al. have compared the congestion in gradient networks generated by either random or scale-free substrates, finding that in the latter case the networks are less prone to jamming[53, 54]. Roger et al. thought that the system only behaves efficiently when the amount of packages handled is small enough. The network collapses above a certain threshold and some packages are accumulated. They found that independently of the topology (1D, 2D and Cayley), the collection of models can be split into three groups according to how the network collapses. In the first group, agents deliver more packets as they are more congested, although their capability decreases, and the network never collapses. In the second group, agents deliver always the same number of packets independently of their load number of packets to deliver; this behavior leads to a continuous phase transition. Finally, when agents deliver fewer packets as their loads increase, the transition to the congested phase is discontinuous and the network collapses in an inhomogeneous way giving rise to congestion nuclei[44].

Compared with the potential costs of changing the structure of well-established networked systems, proposals of clever routing criteria seem to be more practical and thus attract much more interest. Daniele et al. tested a trade-off strategy between traffic based and topological based routing on scale-free networks and found that traffic control is useless in homogeneous networks but may be useful in inhomogeneous networks[41]. Gang Yan et al. propose a routing strategy to improve the transportation efficiency on complex networks. Instead of using the routing strategy for shortest path, they give a generalized routing algorithm to find the so-called "efficient path", which considers the possible congestion in the nodes along actual paths. Since the nodes with the largest degree are very susceptible to traffic congestion, an effective way to improve traffic and control congestion can be redistributing traffic load in central nodes to other non-central nodes. Simulation results indicate that the network capability in processing traffic is improved more than 10 times by optimizing the efficient path[46]. Xiang et al. propose a global dynamic routing strategy for network systems based on the information of the queue length of nodes. Under this routing strategy, the traffic capacity is further improved compared with Gang[46]. With time delay of updating node queue lengths and the corresponding paths, the system capacity remains constant, while the travel time for packets increases[48]. Danila et al.'s algorithm balances traffic on a network by minimizing the maximum node betweenness with as little path lengthening as possible, thus being useful in cases when networks are jamming due to queuing overload. By using the resulting routing table, a network can sustain significantly higher traffic without jamming than in the case of traditional shortest path routing[47]. Tan Fei et al. proposed a routing algorithm that combines static structural properties and dynamic traffic conditions together and therefore can balance the traffic between hubs and peripheral nodes more effectively[49]. Guan et al. focus their research on traffic dynamics of a spatial scale-free network with the restriction of bandwidth proportional to link Euclidean distance, and a new routing strategy is proposed with consideration of both Euclidean distance and betweenness centralities (BC) of edges. It is found that compared with the shortest distance path (SDP) strategy and the minimum betweenness centralities (MBC) of links strategy, their strategy under some parameters can efficiently balance the traffic load and avoid excessive traveling distance which can improve the spatial network capacity and some system behaviors reflecting transportation efficiency, such as average packets traveling time, average packets waiting time and system throughput, traffic load and so on[51].

In practice it is often difficult to change a network's routing protocol or topology. The above works have assumed that all nodes or links are assigned with uniform resources. This simplified scenario allows researchers to study the pure contribution of the routing algorithms and the topology. However it is unrealistic as in real networks resources are rarely distributed uniformly. Zhang et al. come up with a practical and effective approach to allocate the resources in a network such that network elements that handle higher volumes of traffic load have more resources whereas those that handle less load have fewer resources. The results show that their scheme enhances the transmission capacity of networks with heterogeneous structures by up to two orders of magnitude[52].

In recent years, there has been a strong research interest in the Link prediction problem in complex network. The link prediction algorithms can be used to extract missing information, identify spurious interactions, evaluate network evolving mechanisms, and so on. Generally, the link prediction problem is mainly studied from two angles: (i) network structure and (ii) attributes of nodes and connections. Structure reflects the information about network topology. Majority of the progress in the area of structure based prediction has been made by mathematicians and physicists. Some of the well known structure based prediction methods are Common Neighbor, Preferential Attachment Index, Adamic-Adar Index, Katz, etc. The link prediction problem also has been studied from the angle of the network attribute information. The majority of attribute based prediction methods follow a machine learning approach, i.e. they use classification based methods to make predictions. Authors [14–18] report that the performance of link prediction improves when machine learning approaches are used. However, this is done by using additional

network information that is not always available. Since the attribute of nodes is hard to achieve, so in our research we mainly focus on network structure algorithms. Link prediction has been applied in the analysis of social networks, biological networks such as protein-protein interaction networks, metabolic networks and food webs, personalized recommendation, etc[22–27].

With the rapidly development of modern society, the traffic problem has attracted a lot of attention. Most of the previous study in transportation mainly focus on the design of the transportation routes, proposals of clever routing strategies or resource allocation, while it can't avoid congestion totally. Once the transportation system become congested, we need to find a way to solve it, our goal is to find the optimal sequence to recover the routes which can best enhance the traffic flow on the routes. We think that in the status of congestion the traffic in the route almost Stagnated, so to some degree it equals the routes has been broken. Inspired by link prediction, we ranked the congested traffic routes(BA network, USAir, Road network) and recover the routes in order.

Our contributions are as folds. Firstly, we introduce the link prediction methods into traffic congestion problem, previous studies mainly focus on topology, routing strategy and resource allocation, and these works mainly on the prevent of congestion, but even the best strategy can't avoid congestion totally, so we got the necessity to solve the congestion problem once it occurs. Secondly, we propose a third order similarity link prediction algorithm for the first time. Thirdly, we find that "negative ways" perform better than the random recover of routes, random way are better than "positive ways" which is obviously since "negative ways" and "positive ways" are reverse methods. Finally, varies experiments proves that larger network can improve negative link prediction methods' accuracy; Higher degree heterogeneity improves experiment accuracy also, so negative methods are effective especially for BA like topological; At a high level of congested routes like half of the routes have been broken, negative methods almost have accuracy of 100% in the routes recovery sequences discovery.

## RELATED WORK

The simplest framework of link prediction methods is the similarity-based algorithm, where each pair of nodes  $x$  and  $y$ , is assigned a score  $s_{xy}$ , which is directly defined as the similarity between  $x$  and  $y$ . Similarity-based algorithm are classified into three categories: local indices; global indices; quasi-local indices, which do not require global topological information but make use of more information than local indices[28]. Considered of computation complexity here in our experiment we use two classic algorithm: PA in local indices and LP in quasi-local indices and other transformed algorithms.

(1) Preferential Attachment Index (PA)[29]. The mechanism of preferential attachment can be used to generate evolving scale-free networks, where the probability that a new link is connected to the node  $x$  is proportional to  $k_x$ . A similar mechanism can also lead to scale-free networks without growth, where at each time step, an old link is removed and a new link is generated. The probability that this new link will connect  $x$  and  $y$  is proportional to  $k_x k_y$ . Motivated by this mechanism, the corresponding similarity index can be defined as

$$S_{xy} = k_x * k_y \quad (1)$$

(2) Local Path Index (LP)[30, 31]. Denote by  $A$  the adjacency matrix, where  $A_{xy} = 1$  if  $x$  and  $y$  are directly connected, and  $A_{xy} = 0$  otherwise. Obviously,  $(A^2)_{xy}$  is the number of common neighbors of nodes  $x$  and  $y$ , which is also equal to the number of different paths with length 2 connecting  $x$  and  $y$ . And if  $x$  and  $y$  are not directly connected,  $(A^3)_{xy}$  is equal to the number of different paths with length 3 connecting  $x$  and  $y$ . The information contained in  $A^3$  can be used to break the degeneracy of the states, and thus we define a new measure as

$$S = A^2 + \varepsilon A^3 \quad (2)$$

The score of  $S_{xy}$  correspond to the element is  $S$ . And in our experiment we set  $\varepsilon = 0.2$ .

(3) Three order Similarity Index (SA). This algorithm are proposed in this study, the purpose was to magnify the recovery accuracy of the traffic routes.  $\Gamma^3(x)$  means the set of first order neighbor second order neighbor and third order neighbor in all.

$$S_{xy} = |\Gamma^3(x) \cap \Gamma^3(y)| \quad (3)$$

**The followed four algorithm are the transformer of the above three algorithm.**

(4) Reverse Preferential Attachment Index (RPA). simply put the numerator into denominator, which means nodes with less neighbors play a more important role.

$$S_{xy} = \frac{1}{k_x \times k_y} \quad (4)$$

(5) Reverse Add Preferential Attachment Index (RAPA). One different from RPA is that at the denominator part we transfer multiply into add.

$$S_{xy} = \frac{1}{k_x + k_y} \quad (5)$$

(6) Reverse Local Path Index (RLP). simply put the numerator into denominator

$$S = \frac{1}{A^2 + \varepsilon A^3} \quad (6)$$

The score of  $S_{xy}$  correspond to the element is S. And in our experiment we set  $\varepsilon = 0.2$ .

(7) Reverse Three order Similarity Index (RSA). simply put the numerator into denominator

$$S_{xy} = \frac{1}{|\Gamma^3(x) \cap \Gamma^3(y)|} \quad (7)$$

## DATASETS

To verify our methods, we have conducted varies experiments on three kinds of networks. The networks are as below:

### BA network

we select the Barabasi-Albert (BA)[32] model to generate the topological network, the degree distribution of which is a power law  $p(k) \propto k^{-3.0}$  where  $p(k)$  is the ratio of the nodes with degree  $k$  to the number of all nodes in the network. The model could represent the heterogeneous node degree of many real-world networks, including the Internet AS level topology, the logical topology of unstructured P2P distributed systems, and so on. In the simulation, we set the mean degree of the network  $k=4$ .

### USAir

We got USAir data from pajek datasets, The network is extracted from the USAir transportation system. The data contains 332 nodes and 2126 edges. Nodes in the network are individual cities and edges are airlines between these cities. Notice that this is a undirected network which means if you can buy a ticket from city A to city B then you can also buy a ticket from city B to city A. In some degree, USAir is a kind of BA network, some major City like New York and Los Angeles owns more airlines than small cities.

### California road network

The dataset was obtained from Stanford dataset. The original data contains 1,965,206 nodes and 2,766,607 edges. Considered the network is too large for link prediction and traffic simulation, so we split out some small part from the California road network. First we randomly choose a node and take it as the center node, then we use Level Traverse method to spread the network out and we can get different size of road network for our needs. For example, if we take nodeId= 100 as the center node, then we select the node 100s neighbor and append them into the new network, then append the 100s neighbors Neighbor, and the next steps are as before. In California road network, if we choose nodeId= 800120 as the center node and the spread level is 30 we can get a network with 1285 nodes and 1748 edges.

**The basic topology statistics of the six networks are summarized in Table I.**

$|V|$  is the number of vertices and  $|E|$  is the number of edges in a given network.  $D$  denotes the density of the network which is to calculate  $\frac{2|E|}{|V-1|*|V|}$ . A nodes clustering coefcient states that, if there are  $k_i$  neighbors owned by a vertex  $v_i$  and the maximal feasible edges among them could be  $k_i * (k_i - 1) / 2$ , the local clustering coefcient for the vertex  $v_i$  is to calculate  $C_i = \frac{2|E_i|}{k_i(k_i - 1)}$ , where  $E_i$  stands for the number of neighbors of  $v_i$ .  $C$  denotes the average clustering coefcient.  $\langle k \rangle$  is the average degree of the network. Here, a shortest path is dened as a path connecting two unconnected nodes with least edges and thus the shortest path distance is the number of edges existed within the shortest path.  $\langle d \rangle$  denotes the average shortest path distance of the network. Degree heterogeneity is a statistical property, which quantitatively characterizes the fluctuation of the degree sequence of a network. This property was frequently mentioned, while its explicit definition was not manifested until a recent work[33]. To be consistent with previous studies, we denote the degree heterogeneity by  $H$ .  $H$  is defined as  $\frac{2|E|}{|V-1|*|V|}$ , where  $\langle k \rangle$  denotes the average degree[34].

	$ V $	$ E $	D	C	$\langle k \rangle$	$\langle d \rangle$	H
BA256	256	508	0.016	0.075	3.97	3.49	2.17

TABLE I: statistics of the six networks.

## EXPERIMENT

In this section we will give our method to improve the transmission efficiency of the traffic network, show the simulation results, and then discuss them extensively.

### 1. Method

1) In order to test our method we should generate traffic-like topological networks. Here we got three kinds of networks, BA network, USAir network and California road network. To simplify the simulation, they are set to be unweighted and undirected.

2) The next step is to simulate the congestion of the traffic net. We think that in the status of congestion the traffic in the route almost Stagnated, so to some degree it equals the route has been broken. So in this process we randomly select a part of the route, and break them up. Notice that we allow the situation that after the break of the network, there are exists individual nodes.

3) Since we have broken links, so we can use link prediction methods to rank the edges of nonexist, and determine the sequence of recovery links. One different from link prediction is that in link prediction we will rank all the edges of nonexist while in route recovery we just need to judge the important of broken edges and recover them in order. Here we have eight methods to recover the routes which was mentioned before.

4) To verify the efficiency of different methods based on link prediction, we have conducted package simulation experiments. Several models have been proposed to simulate packet traffic dynamics on complex networks by introducing random generation of packets in each time step and various routing strategies. We here adopt one widely used before.

**In each time step**, each node generates  $\frac{R}{N}$  packets, where  $N$  is the size of the network and  $R$  is a parameter tuning the generation rate, i.e., there are  $R$  packets generated in the network at each step. When  $\frac{R}{N}$  is not an integer, we create  $\text{Int}(\frac{R}{N})$  packets determinately and create a packet simultaneously with probability  $p = \frac{R}{N} - \text{Int}(\frac{R}{N})$ , where  $\text{Int}(\frac{R}{N})$  is the integral part of  $\frac{R}{N}$  and thus  $p$  is the fractional part. The packets are initialized with random destinations. Moreover, we set a transmission capacity  $C_i$  to the node  $i$ ,  $i=1,2, \dots, N$ , which means that, at each time step, the maximal number of packets transferred by the node  $i$  to the next node according to the routing table is  $C_i$ . When the node cannot transfer all the packets accumulated in its queue, it deals with them following the rst-in-rst-out rule. Hence, the routing strategy also plays an important role in the traffic dynamics. We see that, in the Internet, the routing strategy of within domains is the shortest path algorithm and, between domains, i.e., for the AS level, the border gateway protocol causes the packets to be transmitted along almost the shortest path[36]. Therefore, in the paper, we adopt the shortest path routing strategy. When a packet reaches its destination through the shortest path routing, the packet will be deleted from the system. In order to analyze the transition from free flow to a congested state, we use the order parameter presented in previous studies[37],

$$\mu < R \rangle = \lim_{t \rightarrow \infty} \frac{\langle \Delta w \rangle}{R \Delta t} \quad (8)$$

where  $W(t)$  is dened as the number of packets on the network at time step  $t$ , and  $W = W(t+\Delta t) - W(t)$ , with  $\langle \rangle$  indicating averaging over time windows of width  $t$ . In other words, the order parameter represents the ratio between the existing ow and the inow of packets calculated through a long enough time period. Obviously, in the free ow state, i.e., where there is no congestion in the network, the system can deal with the generated packets and thus the existing ow is close to zero. Otherwise, in the congested state, the number of generated packets is too large to be transmitted and the ow existing in the network will also be large, which causes the order parameter to approach 1.

### 2. Metrics for evaluation

We have got eight methods to recovery the links in the network. Different methods get different recovery efficiency. First we initialized an array like `bestPerform = [0, 0, 0, 0, 0, 0, 0, 0]`, the array contains 8 elements and each element correspond to a method, the methods are [Random, PA, RPA, RAPA, LP, RLP, SA, RSA] in order. In a certain

R	5	10	15	20	25	30	35	40	45	50
Order parameter	0.005	0.24	0.34	0.46	0.54	0.60	0.64	0.68	0.70	0.73

TABLE II: Correspond to Fig.2, the average order parameter in different value of R.

congestion situation, we use these different methods to recover the links respectively, when we have finished the recovery of the roads, we will calculate the order parameter  $\mu < R >$ . If one method get a lowest order parameter in this period (recovery process) of time, we will choose the corresponding element in the array bestPerform and add by 1. We will repeat the process in a certain times, and finally count the elements in the bestPerform. If an element got the highest value, then it means that the corresponding methods performs best in the link recovery.

### 3.Result

FIG. 1: In this experiment, we first create a California road network, the data was obtained from stanford Datasets. Intersections and endpoints are represented by nodes and the roads connecting these intersections or road endpoints are represented by undirected edges. The network contains 1,965,206 nodes and 2,766,607 edges. Since the network is too large to process, so we need to select a part of the graph. We randomly choose a node from the network, like nodeId= 800120, then we regard the node as the center node, next we use the center node to spread out the network, just like BFS algorithm. Here in this experiment, we set the spread level equals 15, and we get the network with 223 nodes and 291 edges.

Since road network has the lowest heterogeneity among BA and USAir, the degree of the nodes in the network mainly lies in 1,2,3,4,5, so it is hard to identify the important of the edges. But from 10,000 round of comparison, our experiment still reveals the Negative Correlation effect in road network. RPA, RAPA, RLP, RSA performs better than random way, and PA, LP, SA performs badly. From the fig1, we can observe that RSA performs best, I think this may be the reason that we have fully utilize the information of one node in the situation of low heterogeneity. This phenomenon also remind us to use more similarity information to improve the performance of road recovery.

FIG. 2: In order to verify the robust of different methods. We have controlled the value of R. In the above experiment, we create a USAir network, it has 332 nodes and 2126 edges. We then set the ratio of destroyed edges equals to 0.05. Under different R, we got the algorithm's performance as above.

USAir is a kind of transportation system. We can see RAPA always performs best, then follows as RLP, RSA. With the increasement of R, although negative way still performs better, but the gap between positive and negative ways are becoming smaller, the reason for this phenomenon may be that at a very small value of R, the congestion level of the roads are not serious, so the recovery of the roads can release the congestion level a lot. But with the increase of R and congestion, the recovery of roads can't change the congestion situation a lot, so the difference between the recovery methods isn't as big as above. Since the performance of negative ways overwhelms positive link prediction methods under different traffic flow rate, so our methods proves to be robustness. Since normal traffic system won't be too congested, so negative methods can be far more better than random recover the routes.

FIG. 3: In order to know how congestion ratio affect the recovery of traffic. We have generate a BA network with 256 nodes and 508 edges, x-axis represent the ratio of congested route. In the above picture, 0.04 means there are  $\text{int}(0.04 \times 508)$  edges have been congested. Y-axis represent the accurate prediction sequences in 1000 round experiment. The packages generated in one time step is 10.

A lot of traffic system can be modeled as BA network. From fig.3 we can see with the increasement of fraction ratio, negative recovery methods perform far more better than random method and positive one's. At the fraction ratio of 0.4, in 1000 round experiment, RSA method performs best in about 600 round comparison, RPA and RAPA performs about 200 round best respectively while other methods almost have no chance in the guidance of traffic recovery. I think there are two reason for the result, with the increasement of fraction ratio, the recovery sequences have more combination so we can differentiate them more easily. Another reason is that big fraction ratio requires more time in the recovery process, in a larger period of time, we can verify our methods more easily.

FIG. 4: To test our methods in different size of networks, we have generate five BA networks, they contain nodes with 100, 200, 300, 400, 500 respectively. The probability for each node to generate a package in one time step is 0.02 and the fraction ratio is 0.05.

In fig.4 we can see that when the network contains 100 nodes, eight methods haven't much difference in the traffic recovery, this is mainly because that at a very small network there are no big difference for each node so we can't distinguish them clearly. But when the size of the net reaches a certain scale nodes in the network play roles quite differently, hub nodes and normal nodes can't be the same. When the size of BA network reaches 200, the difference of performance can be observed easily. With the increasement of BA size, negative recovery methods perform better than random method and positive methods. At the size of 500, positive ways almost have no chance in accurately recover the routes in a certain sequence. The reason for that negative methods in larger BA network plays better mainly because the larger BA network has larger heterogeneity, so the nodes play roles differently and we can distinguish them more easily. Normally traffic system won't be too small, they usually contain nodes over 200, so our negative ways can be of use in routes recovery especially the reverse similarity(RSA) method.

## CONCLUSION

Traffic problem affect the operation efficiency of the society, current study mainly focus on add new route or rebuild the network. But even the best system can't avoid congestion entirely. Our methods mainly focus on how to recover the routes sequences in a certain order to minimize the negative impact. Inspired by link prediction methods, we have recovered the the route in three strategies. These strategies are positive ways which include PA, LP and SA; negative ways which include RPA, RAPA, RLP and RSA; random way. From our experiment we find that negative ways perform better than the random recover of routes, random way are better than positive ways which is obviously since negative ways and positive ways are reverse methods. Beside the verification of negative link prediction methods

in routes recovery. We also find that larger network can improve negative link prediction methods' accuracy; Higher degree heterogeneity improves experiment accuracy also, so negative methods are effective especially for BA like topological; At a high level of congested routes like half of the routes have been broken, negative methods almost have accuracy of 100% in the routes recovery.

Our study is tentative in using link prediction methods solving traffic problem, our result shows a tremendous potential combine link prediction methodology and real traffic problem. Since few people have doing researches in this field, so there are many shortcomings to be further optimized. In lack of real traffic flow data, so we simplified our simulation with a certain rate of packages generated in a certain time step. If possible, further studies can obtain real traffic flow and doing recovery experiment. Also weighted networks deserve to be discussed. In all, our research have found some simple ways to recover the congested ways efficiently, this may a new branch in the traffic problem.
